Introduction
Round pneumonia has been defined as an oval or round-shaped consolidation distributed in a nonsegmental pattern, found mostly in children. Owing to its radiological appearances, it stimulates bronchogenic carcinoma particularly in adults. We present a case of tubercular round pneumonia mimicking malignancy, treated successfully by antitubercular drugs.

Case history
A 40-year-old nonsmoker, nondiabetic male patient was referred to us as a case of nonresolving pneumonia with an antecedent 2 months history of right-sided chest pain and fever. The available chest radiography (Fig. 1) was suggestive of a circumscribed consolidation over the right lower zone. His medical history had been uneventful. Viral markers were nonreactive. Total leukocyte counts were normal (7700/cm\textsuperscript{3}). Patient was subject to repeat sputum examinations for gram staining and acid-fast bacilli staining, both of which could not help with the diagnosis. Computed tomography (CT) scan (Figs 2 and 3) was ordered which revealed a well-defined thick-walled lesion (9×8.9×8.1 cm in size) involving lower lobe of right lung with air specks. In view of the mass-like picture, a CT-guided transthoracic fine-needle aspiration cytology/aspirate/biopsy was done. Biopsy of the lung mass revealed granulomatous inflammation consistent with tubercular etiology. The patient was started on standard four-drug regimen of rifampicin, isoniazid, ethambutol, and pyrazinamide according to weight. Follow-up was done using serial chest radiographies every month. A favorable response was seen, as chest pain and fever improved. Treatment was extended to 12 months on stopping pyrazinamide after 3 months. After 12 months of therapy, a follow-up chest radiography (Fig. 4) and CT scan (Figs 5 and 6) showed that the process had resolved. There was near-complete resolution of the rounded mass on imaging studies. Patient was asymptomatic and gained weight and appetite. Anti tubercular therapy (ATT) was stopped, and patient was kept on routine follow-up.

Round pneumonia is a condition usually seen in children, with very few reports recorded in adult patients. It is a type of acute infective pneumonia with a round-shaped consolidation area radiologically [1]. It simulates pulmonary masses both clinically and radiologically. Round pneumonia can be difficult to distinguish from bronchogenic carcinoma particularly in adults. Round pneumonias are roundish and although they are well-circumscribed parenchymal opacities, they tend to have irregular margins. The typical location is the posterior and lower lobe [2].

Streptococcus pneumonia is the most common pathogen of spherical pneumonia in both adults and children, and other pathogens include Klebsiella pneumoniae, Haemophilus influenzae, and...
Mycobacterium tuberculosis [3]. Unusual radiographic patterns in pulmonary tuberculosis presenting with mass-like densities, most of which were initially and mistakenly diagnosed as neoplasm, have been uncommonly seen in the past [4]. Round pneumonia should be suspected in an adult patient who presents with a pulmonary mass, especially if he has respiratory infection symptoms, is a young nonsmoker, and has no other findings to suggest malignancy. Any patient with a pulmonary nodule that does not decrease in size or resolution after antibiotic treatment should be further assessed with bronchoscopy or transthoracic needle biopsy.

Tuberculosis continues to be a major cause of morbidity and mortality worldwide. There has been a steady rise in the number of tubercular patients with radiological and clinical characteristics stimulating malignancy accentuating the problem of accurate diagnosis of tuberculosis and malignancy. There are many similarities between both diseases; both are highly prevalent, involve lung parenchyma, and are characterized by similar symptoms. Symptoms such as fever, cough, expectoration, hemoptysis, weight loss, and anorexia are common to both tuberculosis and lung cancer. Owing to high prevalence of tuberculosis in India and radiological similarities, many patients with lung cancer initially get wrongly diagnosed and treated for pulmonary tuberculosis, and there appears to be an unacceptable delay during the diagnosis and treatment of lung cancer. When a combination of clinical, laboratory, and imaging findings does not help to exclude malignancy, transthoracic biopsy can to lead to a correct diagnosis. This helps to start appropriate therapy.
